Designing for Performance

- The cost of computer systems continues to drop dramatically, while the performance and capacity of those systems continue to rise equally dramatically
- Today's laptops have the computing power of an IBM mainframe from 10 or 15 years ago
- Processors are so inexpensive that we now have microprocessors we throw away
- Desktop applications that require the great power of today's microprocessor-based systems include:
  - Image processing
  - Three-dimensional rendering
  - Speech recognition
  - Videoconferencing
  - Multimedia authoring
  - Voice and video annotation of files
  - Simulation modeling

- Businesses are relying on increasingly powerful servers to handle transaction and database processing and to support massive client/server networks that have replaced the huge mainframe computer centers of yesteryear
- Cloud service providers use massive high-performance banks of servers to satisfy high-volume, high-transaction-rate applications for a broad spectrum of clients

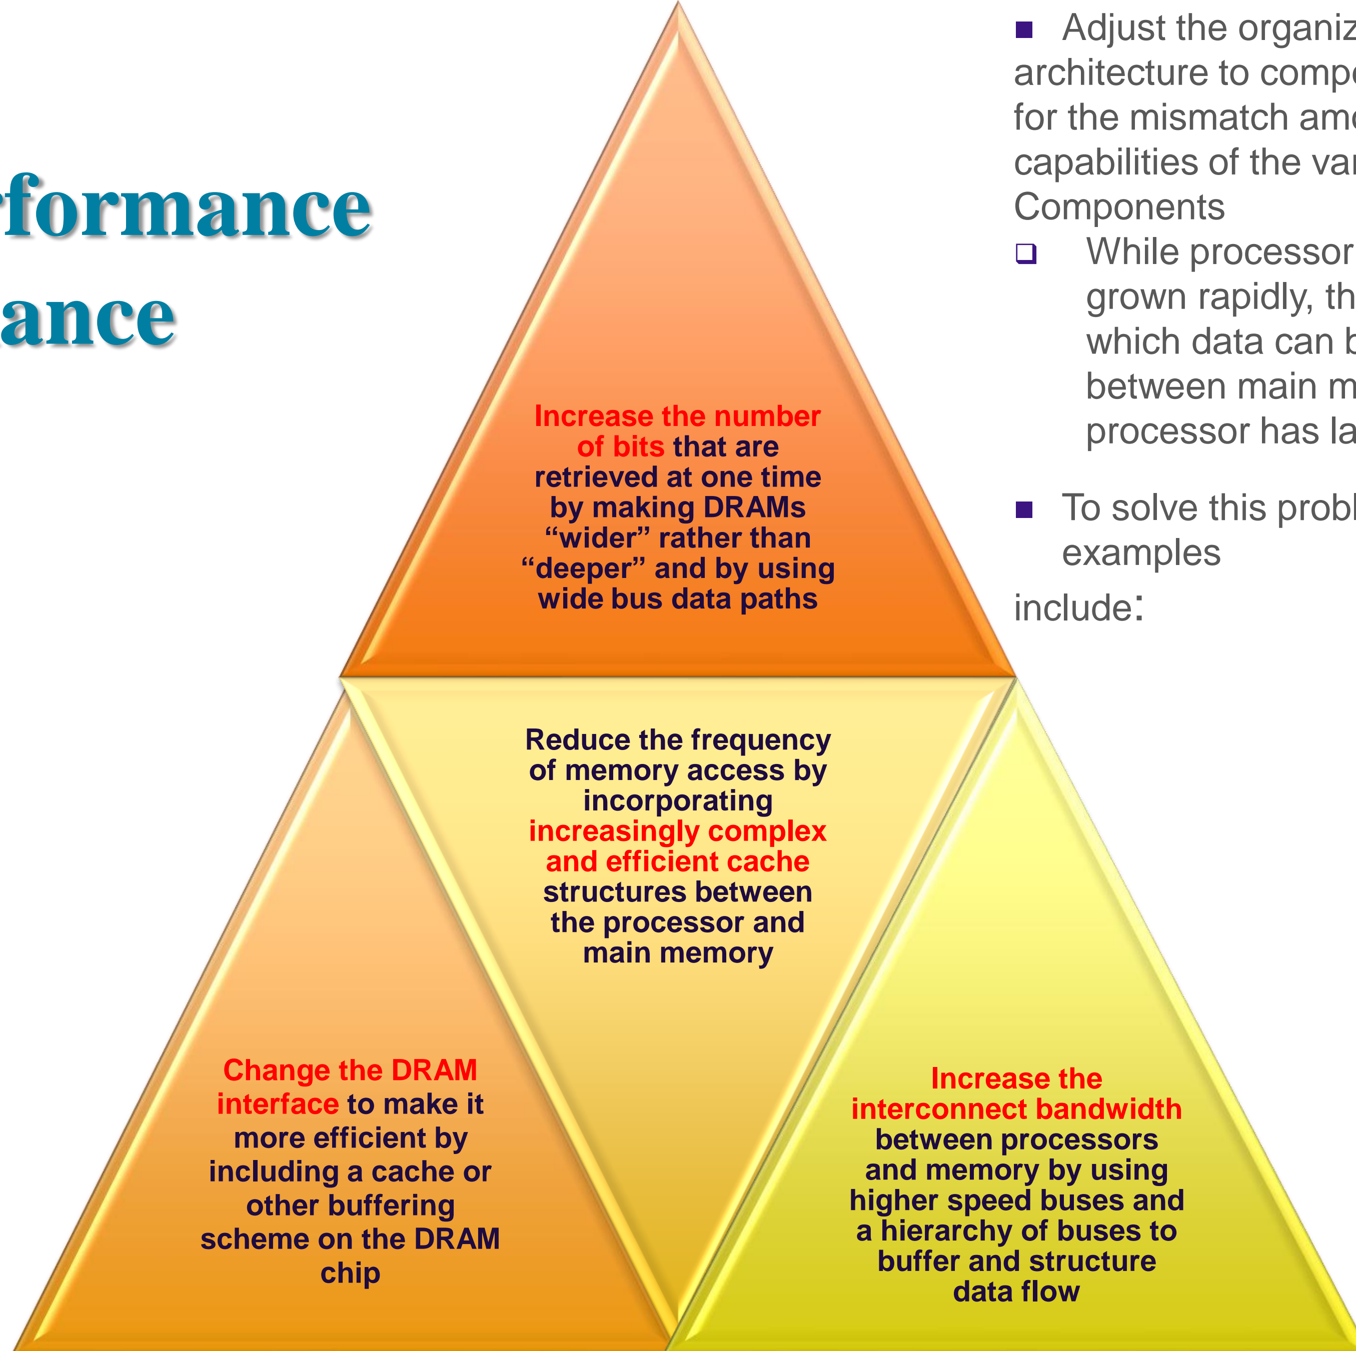
Performance Balance



- Adjust the organization and architecture to compensate for the mismatch among the capabilities of the various Components
  - While processor speed has grown rapidly, the speed with which data can be transferred between main memory and the processor has lagged badly.
- To solve this problem, architectural examples include:

Another area of design focus is the handling of I/O devices. As computers become faster and more capable, more sophisticated applications are developed that support the use of peripherals with intensive I/O demands.

Improvements in Chip Organization and Architecture

- Increase hardware speed of processor
  - Fundamentally due to shrinking logic gate size
    - More gates, packed more tightly, increasing clock rate
    - Propagation time for signals reduced
- Increase size and speed of caches
  - Dedicating part of processor chip
    - Cache access times drop significantly
- Change processor organization and archit
  - Increase effective speed of instruction execution
  - Parallelism

Problems with Clock Speed and Logic Density

- Power
  - Power density increases with density of logic and clock speed
  - Dissipating heat
- RC delay
  - Speed at which electrons flow limited by resistance and capacitance of metal wires connecting them
  - Delay increases as the RC product increases
  - As components on the chip decrease in size, the wire interconnects become thinner, increasing resistance
  - Also, the wires are closer together, increasing capacitance
- Memory latency
  - Memory speeds lag processor speeds

Processor Trends

- Simply relying on increasing clock rate for increased performance runs into the power dissipation problem. The faster the clock rate, the greater the amount of power to be dissipated, and some fundamental physical limits are being reached.

- Beginning in the late 1980s, and continuing for about 15 years, two main strategies have been used to increase performance beyond simply by increasing clock speed.
  - increasing cache capacity. There are now typically two or three levels of cache between the processor and main memory
  - parallel execution of instructions within the processor by pipelining and superscalar execution

- By the mid to late 90s, both of these approaches were reaching a point of diminishing returns. The internal organization of contemporary processors is exceedingly complex and is able to squeeze a great deal of parallelism out of the instruction stream. The benefits from the cache are also reaching a limit.

- To continue to increase performance, designers have had to find ways of exploiting the growing number of transistors other than simply building a more complex processor.
  - The response in recent years has been the development of the multicore computer chip.

The use of multiple processors on the same chip provides the potential to increase performance without increasing the clock rate

Strategy is to use two simpler processors on the chip rather than one more complex processor

With two processors larger caches are justified

As caches became larger it made performance sense to create two and then three levels of cache on a chip

Many Integrated Core (MIC) Graphics Processing Unit (GPU)

MIC

- A large number of cores (sometimes more than 50)have led to the introduction of a new term: many integrated core (MIC).
- Leap in performance as well as the challenges in developing software to exploit such a large number of cores
- The multicore and MIC strategy involves a homogeneous collection of general purpose processors on a single chip

GPU

- Core designed to perform parallel operations on graphics data
- Traditionally found on a plug-in graphics card, it is used to encode and render 2D and 3D graphics as well as process video
- Used as vector processors for a variety of applications that require repetitive computations

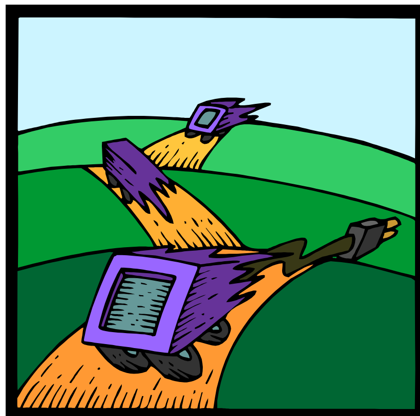
Amdahl's Law



- proposed by Gene Amdahl
- Deals with the potential speedup of a program using multiple processors compared to a single processor
- Illustrates the problems facing industry in the development of multi-core machines
- Software must be adapted to a highly parallel execution environment to exploit the power of parallel processing
- Can be generalized to evaluate and design technical improvement in a computer system

Consider a program running on a single processor such that a fraction (1 – *f)* of the execution time involves code that is inherently serial and a fraction f that involves code that is infinitely parallelizable with no scheduling overhead. Let *T* be the total execution time of the program using a single processor. Then the speedup using a parallel processor with *N* processors that fully exploits the parallel portion of the program

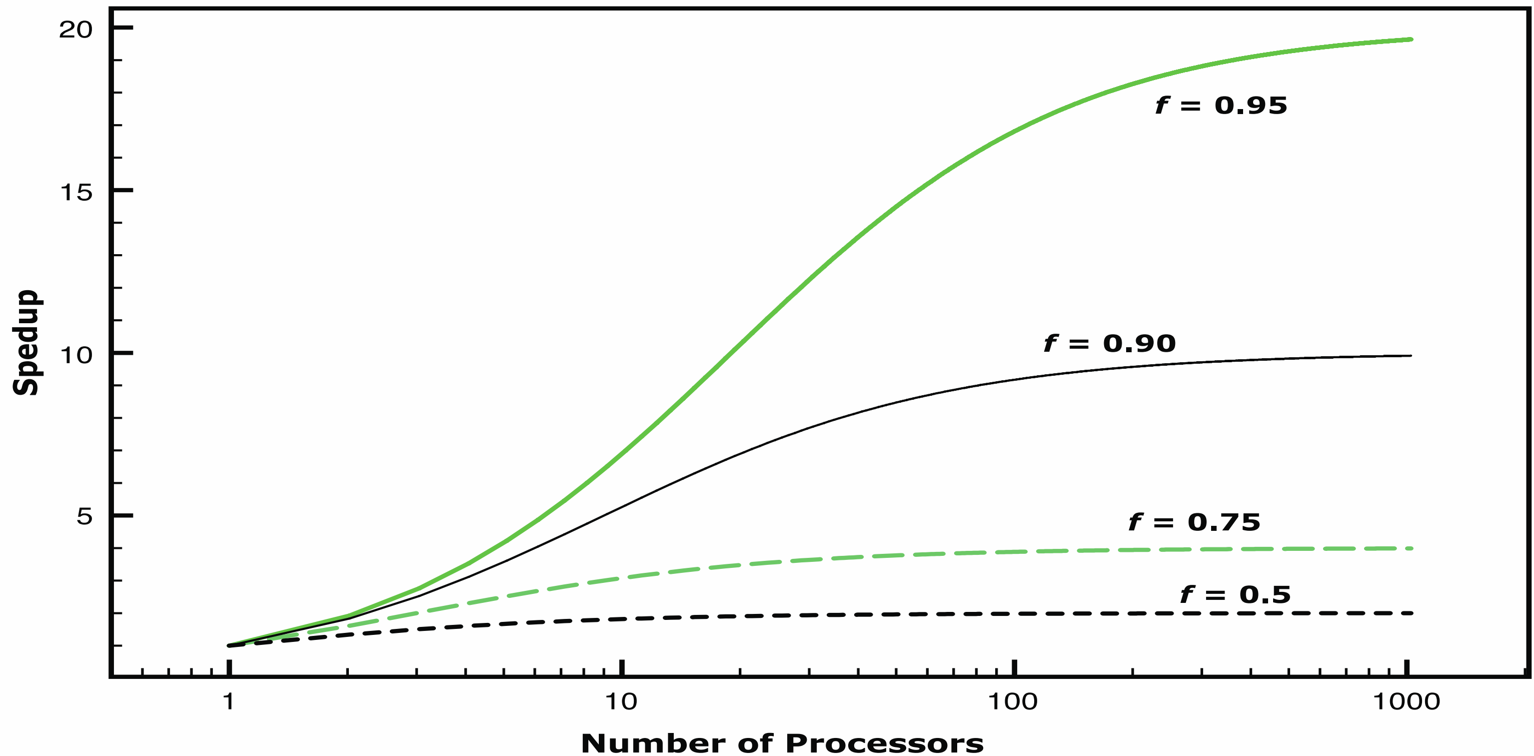

Figure 2.4 Amdahl's Law for Multiprocessors

1. When *f is small, the use of parallel processors has little effect.*
2. As *N approaches infinity, speedup is bound by 1/(1 – f), so that there are* diminishing returns for using more processors.

Little's Law

- Fundamental and simple relation with broad applications
- Can be applied to almost any system that is statistically in steady state, and in which there is no leakage
- Queuing system
  - If server is idle an item is served immediately, otherwise an arriving item joins a queue
  - There can be a single queue for a single server or for multiple servers, or multiple queues with one being for each of multiple servers
- Average number of items in a queuing system equals the average rate at which items arrive multiplied by the time that an item spends in the system
  - Relationship requires very few assumptions
  - Because of its simplicity and generality it is extremely useful
- Example: Little's Law tells us that the average number of customers in the store L, is the effective arrival rate λ, times the average time that a customer spends in the store W, or simply:

$$L = \lambda * W$$

Assume customers arrive at the rate of 10 per hour and stay an average of 0.5 hour. This means we should find the average number of customers in the store at any time to be 5.

$$L = 10 * 0.5 = 5$$

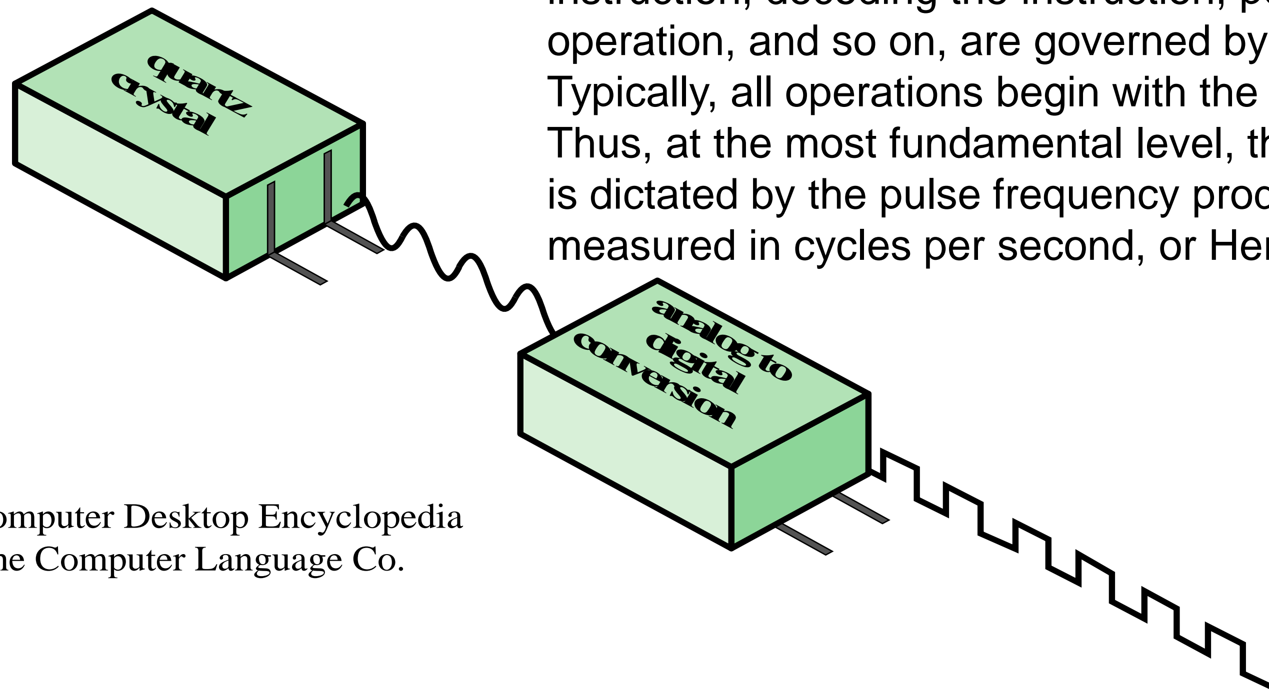
Operations performed by a processor, such as fetching an instruction, decoding the instruction, performing an arithmetic operation, and so on, are governed by a system clock. Typically, all operations begin with the pulse of the clock. Thus, at the most fundamental level, the speed of a processor is dictated by the pulse frequency produced by the clock, measured in cycles per second, or Hertz (Hz).



From Computer Desktop Encyclopedia
1998, The Computer Language Co.

Figure 2.5 System Clock

Typically, clock signals are generated by a quartz crystal, which generates a constant sine wave while power is applied. This wave is converted into a digital voltage pulse stream that is provided in a constant flow to the processor circuitry (Figure 2.5). For example, a 1-GHz processor receives 1 billion pulses per second. The rate of pulses is known as the **clock rate, or clock speed.** One increment, or pulse, of the clock is referred to as a clock cycle, or a clock tick. The time between pulses is the **cycle time.**

Instruction Execution Rate

- A processor is driven by a clock with a constant frequency f or, equivalently, a constant cycle time t, where

$$t = 1/f.$$

- The processor time T needed to execute a given program can be expressed as

$$T = I_c * CPI * t$$

- The instruction count, I_c, for a program, is the number of machine instructions executed for that program until it runs to completion or for some defined time interval.
- An important parameter is the average cycles per instruction (CPI) for a program. (The number of clock cycles required varies for different types of instructions. CPI is the average)

Pearson

Copyright © 2022 Pearson Education, Ltd. All Rights Reserved

Instruction Execution Rate

- We can refine the formulation for processor time T by recognizing that during the execution of an instruction, part of the work is done by the processor, and part of the time a word is being transferred to or from memory

$$T = I_c * [p + (m * k)] * t \qquad \text{where}$$

- p is the number of processor cycles needed to decode and execute the instruction,
- m is the number of memory references needed, and
- k is the ratio between memory cycle time and processor cycle time.
- The five performance factors in the preceding equation (I_c, p, m, k, t) are influenced by four system attributes:
  - the design of the instruction set (known as *instruction set architecture*);
  - compiler technology (how effective the compiler is in producing an efficient machine language program from a high-level language program);
  - processor implementation;
  - and cache and memory hierarchy.

MIPS and MFLOPS Rate

A common measure of performance for a processor is the rate at which instructions are executed, expressed as millions of instructions per second (MIPS), referred to as the **MIPS rate**. We can express the MIPS rate in terms of the clock rate and *CPI* as follows:

$$\text{MIPS rate} = \frac{I_c}{T \times 10^6} = \frac{f}{CPI \times 10^6} \qquad \textbf{(2.3)}$$

Another common performance measure deals only with floating-point instructions. These are common in many scientific and game applications. Floating-point performance is expressed as millions of floating-point operations per second (MFLOPS), defined as follows:

$$\text{MFLOPS rate} = \frac{\text{Number of executed floating} - \text{point operations in a program}}{\text{Execution time} \times 10^6}$$

Pearson Copyright © 2022 Pearson Education, Ltd. All Rights Reserved

MIPS Rate example

EXAMPLE 2.2 Consider the execution of a program that results in the execution of 2 million instructions on a 400-MHz processor. The program consists of four major types of instructions. The instruction mix and the *CPI* for each instruction type are given below, based on the result of a program trace experiment:

Instruction Type	*CPI*	Instruction Mix (%)
Arithmetic and logic	1	60
Load/store with cache hit	2	18
Branch	4	12
Memory reference with cache miss	8	10

The average *CPI* when the program is executed on a uniprocessor with the above trace results is $CPI = 0.6 + (2 \times 0.18) + (4 \times 0.12) + (8 \times 0.1) = 2.24$. The corresponding MIPS rate is $(400 \times 10^6)/(2.24 \times 10^6) \approx 178$.

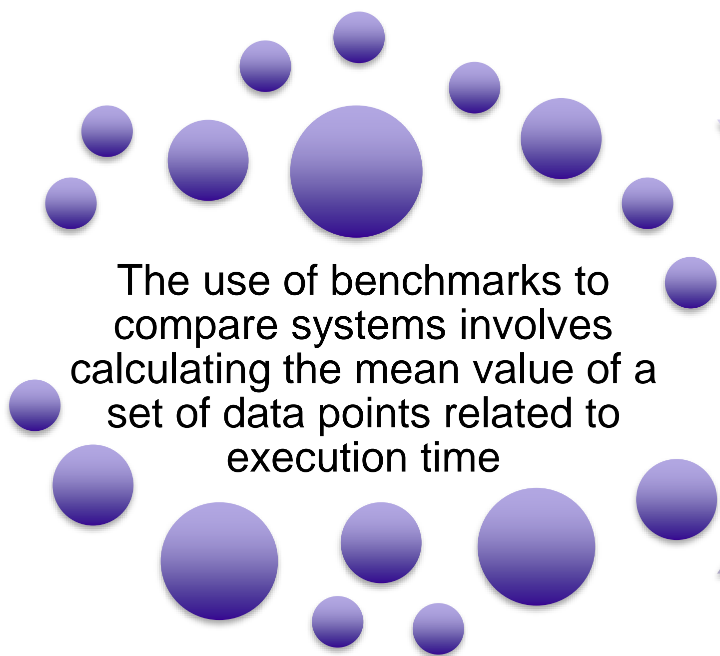
Calculating the Mean



The three common formulas used for calculating a mean are:

- Arithmetic
- Geometric
- Harmonic

© 2016 Pearson Education, Inc., Hoboken, NJ. All rights reserved.

Pearson

Copyright © 2022 Pearson Education, Ltd. All Rights Reserved

Arithmetic mean

$$AM = \frac{x_1 + \cdots + x_n}{n} = \frac{1}{n}\sum_{i=1}^{n} x_i \quad \textbf{(2.4)}$$

Geometric mean

$$GM = \sqrt[n]{x_1 \times \cdots \times x_n} = \left(\prod_{i=1}^{n} x_i\right)^{1/n} = e^{\left(\frac{1}{n}\sum_{i=1}^{n}\ln(x_i)\right)} \quad \textbf{(2.5)}$$

Harmonic mean

$$HM = \frac{n}{\left(\frac{1}{x_1}\right) + \cdots + \left(\frac{1}{x_n}\right)} = \frac{n}{\sum_{i=1}^{n}\left(\frac{1}{x_i}\right)} \qquad x_i > 0 \quad \textbf{(2.6)}$$

It can be shown that the following inequality holds:

$$AM \geq GM \geq HM$$

We can get a useful insight into these alternative calculations by defining the functional mean. Let $f(x)$ be a continuous monotonic function defined in the interval $0 \leq y < \infty$. The functional mean with respect to the function $f(x)$ for n positive real numbers $(x_1, x_2, \ldots, x_n)$ is defined as

Functional mean $$FM = f^{-1}\left(\frac{f(x_1) + \cdots + f(x_n)}{n}\right) = f^{-1}\left(\frac{1}{n}\sum_{i=1}^{n} f(x_i)\right)$$

where $f^{-1}(x)$ is the inverse of $f(x)$. The mean values defined in Equations (2.1) through (2.3) are special cases of the functional mean, as follows:

- AM is the FM with respect to $f(x) = x$
- GM is the FM with respect to $f(x) = \ln x$
- HM is the FM with respect to $f(x) = 1/x$

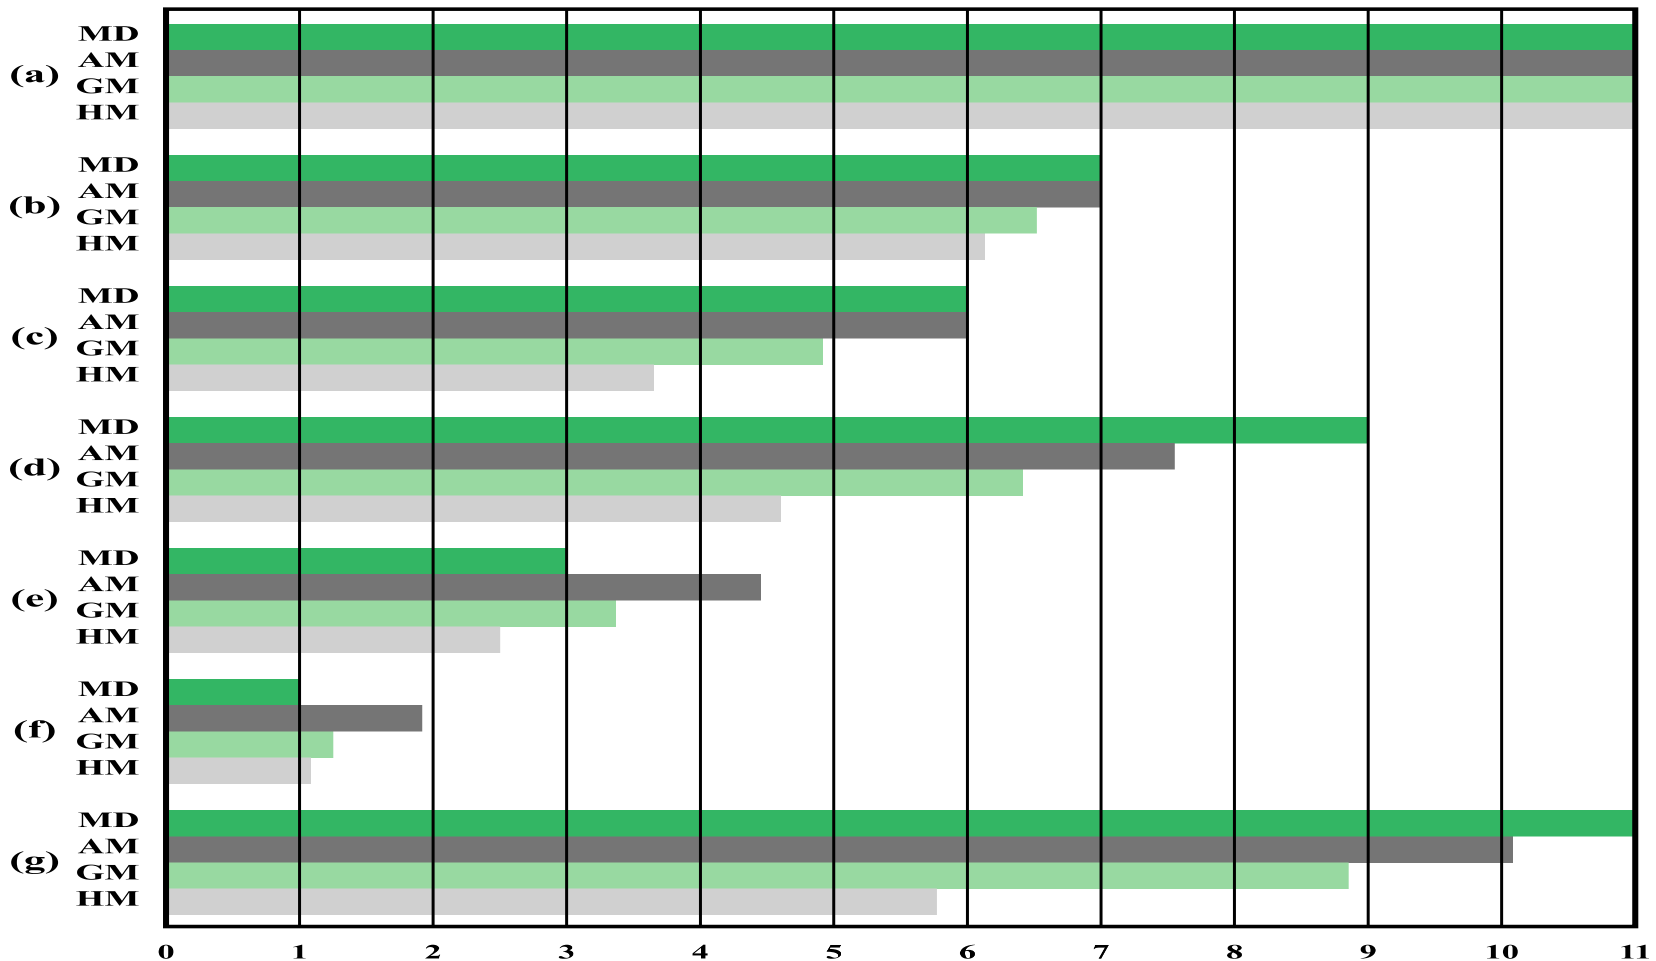


Figure 2.6 Comparison of Means on Various Data Sets (each set has a maximum data point value of 11)

Means

- It is examples like this that have fueled the “benchmark means wars” in the citations listed earlier. It is safe to say that no single number can provide all the information that one needs for comparing performance across systems.
- One is chosen depending upon application.
- SPEC uses GM

Arithmetic Mean

- An Arithmetic Mean (AM) is an appropriate measure if the sum of all the measurements is a meaningful and interesting value

- The AM is a good candidate for comparing the execution time performance of several systems

> For example, suppose we were interested in using a system for large-scale simulation studies and wanted to evaluate several alternative products. On each system we could run the simulation multiple times with different input values for each run, and then take the average execution time across all runs. The use of multiple runs with different inputs should ensure that the results are not heavily biased by some unusual feature of a given input set. The AM of all the runs is a good measure of the system's performance on simulations, and a good number to use for system comparison.

- The AM used for a time-based variable, such as program execution time, has the important property that it is directly proportional to the total time
- If the total time doubles, the mean value doubles

Benchmarks

- The common need in industry and academic and research communities for generally accepted computer performance measurements has led to the development of standardized benchmark suites.
- A benchmark suite is a collection of programs, defined in a high-level language, that together attempt to provide a representative test of a computer in a particular application or system programming area

Benchmark Principles

- Desirable characteristics of a benchmark program:

1. It is written in a high-level language, making it portable across different machines
2. It is representative of a particular kind of programming domain or paradigm, such as systems programming, numerical programming, or commercial programming
3. It can be measured easily
4. It has wide distribution

  - This enables users to attempt to optimize system performance by optimizing the compiler output
- Speed metric
  - This is simply a measurement of the time it takes to execute a compiled benchmark
    - Used for comparing the ability of a computer to complete single tasks
- Rate metric
  - This is a measurement of how many tasks a computer can accomplish in a certain amount of time
    - This is called a throughput, capacity, or rate measure
    - Allows the system under test to execute simultaneous tasks to take advantage of multiple processors

Summary

Chapter 2

Performance Issues

- Designing for performance
- Microprocessor speed
- Performance balance
- Improvements in chip organization and architecture
- Multicore
- MICs
- GPGPUs
- Amdahl's Law
- Little's Law

- Basic measures of computer performance
  - Clock speed
  - Instruction execution rate
- Calculating the mean
  - Arithmetic mean
  - Harmonic mean
  - Geometric mean
- Benchmark principles
- SPEC benchmarks
